Abstract

Hubers et al. [2024] introduce $R\omega\mu$, a higher-order row calculus, but do not describe any metatheory of its type equivalence relation nor of type reduction. $R\omega\mu$ extends System $F\omega\mu$ with rows, records, variants, row mapping, and a novel row complement operator. This paper shows not only that $R\omega\mu$ types enjoy normal forms, but formalizes the normalization-by-evaluation (NbE) of types in the interactive proof assistant Agda. We prove that our normalization algorithm is stable, sound and complete with respect to the type equivalence relation. Consequently, type conversion in $R\omega\mu$ is decidable.

1 Introduction

Hubers and Morris [2023] introduce an expressive higher-order row calculus called R ω , which relies on implicit type reductions according to a directed type equivalence relation. Despite this reliance, the authors only provide a proof of *semantic soundness* that well-typed terms inhabit the denotations of well-kinded types. The authors do not characterize the shape of types in normal form, nor prove that the denoted types are sound and complete with respect to the equivalence relation. Hubers et al. [2024] extends the R ω language to R $\omega\mu$, which is R ω with recursive types, term-level recursion, and a novel *row complement* operator. The authors similarly extend the proof of semantic soundness, and fail to describe any metatheory of the equivalence relation.

1.1 The need for type normalization

R ω and R $\omega\mu$ each have a type conversion rule. The rule below states that the term M can have its type converted from τ to v provided a proof that τ and v are equivalent. (For now, let us split environments into kinding environments Δ , evidence environments Φ , and typing environments Γ .)

$$\text{(t-conv)}\, \frac{\Delta; \Phi; \Gamma \vdash M: \tau \quad \Delta \vdash \tau = v: \bigstar}{\Delta; \Phi; \Gamma \vdash M: v}$$

Conversion rules can complicate metatheory in an intrinsic setting. Hubers and Morris [2023]; Hubers et al. [2024] each provide an intrinsic semantics and do not provide a procedure to decide type checking or type equivalence. Proofs of type conversion are thus necessarily embedded into the term language. This has a number of consequences:

- Users of the surface language are forced to write conversion rules by hand.
- 2. Decidability of type checking now rests upon the decidability of type conversion.
- 3. Term-level conversions can block β -reduction if a conversion is in the head position of an application.
- 4. Term-level conversions can block proofs of progress. Let M have type τ , let pf be a proof that $\tau = v$, and consider the term conv M pf; ideally, one would expect this to reduce to M (we've changed nothing semantically about the term). But this breaks type preservation, as conv M pf (at type v) has stepped to a term at type τ .
- 5. Inversion of the typing judgment $\Delta; \Phi; \Gamma \vdash M : \tau$ —that is, induction over derivations—must consider the possibility that this derivation was constructed via conversion. But conversion from what type? Proofs by induction over derivations often thus get stuck.

All of these complications may be avoided provided a sound and complete normalization algorithm. In such a case, all types are reduced to normal forms, where syntactic comparison is enough to decide equivalence. In effect, the proofs of all conversions have collapsed to just the reflexive case, and so term-level conversions can safely be removed.

1.2 Contributions

This paper offers the following as contributions:

- 1. A normalization procedure for the directed $R\omega\mu$ type equivalence relation;
- 2. a semantics of the type-level *row complement* operator:
- 3. proofs of soundness and completeness of normalization with respect to type equivalence; and
- 4. a complete mechanization in Agda of $R\omega\mu$ and the claimed metatheoretic results.

Figure 1. Syntax

The $\mathbf{R}\omega\mu$ calculus

Type constants

Figure 1 describes the syntax of kinds, predicates, and types in $R\omega\mu$.

Labels (i.e., record field and variant constructor names) live at the type level, and are classified by kind L. Rows of kind κ are classified by R[κ]. When possible, we use ϕ for type functions, ρ for row types, and ξ for label types. Singleton types $\#\tau$ are used to cast label-kinded types to types at kind \star . $\phi \, \, \, \, \, \, \, \rho$ maps the type operator ϕ across a row ρ . In practice, we often leave the map operator implicit, using kind information to infer the presence of maps. We define a families of Π and Σ constructors, describing record and variants at various kinds; in practice, we can determine the kind annotation from context. μ builds isorecursive types. Row literals (or, synonymously, simple rows) are sequences of labeled types $\xi_i > \tau_i$. We write $0 \dots m$ to denote the set of naturals up to (but not including) m. We will frequently use ε to denote the empty row.

The type $\pi \Rightarrow \tau$ denotes a qualified type. In essence, the predicate π restricts the instantiation of the type variables in τ . Our predicates capture relationships among rows: $\rho_1 \lesssim \rho_2$ means that ρ_1 is *contained* in ρ_2 , and $\rho_1 \odot \rho_2 \sim \rho_3$ means that ρ_1 and ρ_2 can be combined to give ρ_3 .

Finally, $R\omega\mu$ introduces a novel row complement operator $\rho_2 \setminus \rho_1$, analogous to a set complement for rows. The complement $\rho_2 \setminus \rho_1$ intuitively means the row obtained by removing any label-type associations in ρ_1 from ρ_2 . In practice, the type $\rho_2 \setminus \rho_1$ is meaningful only when we know that $\rho_1 \lesssim \rho_2$, however constraining the formation of row complements to just this case introduces an unpleasant dependency between predicate evidence and type well-formedness. In practice, it is easy enough to totally define the complement operator on all rows, even without the containment of one by the other.

2.1 Type computation in $R\omega\mu$

 $R\omega$ and $R\omega\mu$ are quite expressive languages, with succinct and readable types. To some extent, this magic relies on implicit type application, implicit maps, and unresolved type reduction. Let us demonstrate with a few examples.

2.1.1 Reifving variants, reflecting records. The following R ω terms witness the duality of records and variants.

```
reify : \forall z : R[\star], t : \star.
               (\Sigma z \rightarrow t) \rightarrow \Pi (z \rightarrow t)
reflect : \forall z : R[ \star ], t : \star.
                  \Pi (z \rightarrow t) \rightarrow \Sigma z \rightarrow t
```

The term reify transforms a variant eliminator into a record of individual eliminators; the term reflect transforms a record of individual eliminators into a variant eliminator. The syntax above is precise, but arguably so because it hides some latent computation. In particular, what does $z \rightarrow t$ mean? The variable z is at kind R[\star] and t at kind \star , so this is an implicit map. Rewriting explicitly yields:

```
reify : \forall z : R[ \star ], t : \star.
                  (\Sigma z \rightarrow t) \rightarrow \Pi ((\lambda s. s \rightarrow t) \$ z)
reflect : \forall z : R[\star], t : \star.
                 \Pi ((\lambda s. s \rightarrow t) \$ z) \rightarrow \Sigma z \rightarrow t
```

The writing of the former rather than the latter is permitted because the corresponding types are convertible.

2.1.2 Deriving functorality. We can simulate the deriving of functor typeclass instances: given a record of fmap instances at type Π (Functor z), we can give a Functor instance for Σ z.

```
type Functor : (\star \to \star) \to \star
type Functor = \lambda f. \forall a b. (a \rightarrow b) \rightarrow f a \rightarrow f b
fmapS : \forall z : R[\star \rightarrow \star].
            \Pi (Functor z) \rightarrow Functor (\Sigma z)
```

When we consider the kind of Functor z it becomes apparent that this is another implicit map. Let us write it explicitly and also expand the Functor type synonym:

```
fmapS : \forall z : R[\star \rightarrow \star].
            \Pi ((\lambdaf. \forall a b.
                 (a \rightarrow b) \rightarrow f a \rightarrow f b) \ \ \ \ z) \rightarrow
             (\lambda f. \ \forall \ a \ b. \ (a \rightarrow b) \rightarrow f \ a \rightarrow f \ b) \ (\Sigma \ z)
```

which reduces further to:

```
fmapS : \forall z : R[\star \rightarrow \star].
                \Pi ((\lambdaf. \forall a b.
                         (a \rightarrow b) \rightarrow f a \rightarrow f b) \ \ \ \ z) \rightarrow
                \forall a b. (a \rightarrow b) \rightarrow (\Sigma z) a \rightarrow (\Sigma z) b
```

Intuitively, we suspect that (Σz) a means "the variant of type constructors z applied to the type variable a". Let us make this intent obvious. First, define a "left-mapping" helper _??_ with kind R[$\star \to \star$] $\to \star \to$ R[\star] as so:

```
r ?? t = (\lambda f. f t) r
```

Now the type of fmapS is:

```
fmapS : \forall z : R[\star \rightarrow \star].
               \Pi ((\lambdaf. \forall a b.
                        (a \rightarrow b) \rightarrow f a \rightarrow f b) \ \ \ \ z) \rightarrow
                \forall a b. (a \rightarrow b) \rightarrow \Sigma (z ?? a) \rightarrow \Sigma (z ?? b)
```

325

326

327

328

329

330

And we have what appears to be a normal form. Of course, the type is more interesting when applied to a real value for z. Suppose z is a functor for naturals, { 'Z > const Unit, 'S $\triangleright \lambda x$. x}. Then a first pass yields:

```
fmapS {'Z > const Unit, 'S > \lambda x. x} :
             \Pi ((\lambdaf. \forall a b. (a \rightarrow b) \rightarrow f a \rightarrow f b)
                \{ 'Z \triangleright const Unit, 'S \triangleright \lambda x. x \} ) \rightarrow
             \forall a b. (a \rightarrow b) \rightarrow
             \Sigma ({'Z > const Unit, 'S > \lambda x. x} ?? a) \rightarrow
             \Sigma ({'Z > const Unit, 'S > \lambda x. x} ?? b)
```

How do we reduce from here? Regarding the first input, we suspect we would like a record of fmap instances for both the 'Z and 'S functors. We further intuit that the subterm ({'Z > const Unit, 'S > λx . x} ?? a) really ought to mean "the row with 'Z mapped to Unit and 'S mapped to a". Performing the remaining reductions yields:

```
fmapS {'Z > const Unit, 'S > \lambda x. x} :
               \Pi \{ 'Z \triangleright \forall a b. (a \rightarrow b) \rightarrow Unit \rightarrow Unit, \}
                         'S \triangleright \forall a b. (a \rightarrow b) \rightarrow a \rightarrow b\} \rightarrow
                \forall a b. (a \rightarrow b) \rightarrow
               \Sigma {'Z > Unit , 'S > a} \rightarrow
                \Sigma \{ 'Z \triangleright Unit , 'S \triangleright b \}
```

The point we arrive at is that the precision of some R ω and $R\omega\mu$ types are supplanted quite effectively by type equivalence. Further, as values are passed to type-operators, the shapes of the types incur forms of reduction beyond simple β -reduction. In this case, we must map type operators over rows; we next consider the reduction of row complements.

2.1.3 Desugaring Booleans. Consider a desugaring of Booleans to Church encodings:

```
type BoolF = { 'T ⊳ const Unit ,
                     'F ⊳ const Unit ,
                     'If \triangleright \lambda x. Triple x x x}
type LamF = { 'Lam ▶ Id ,
                      'App \triangleright \lambda x. Pair x x ,
                     'Var ⊳ const Nat }
desugar : \forall y. BoolF \lesssim y, LamF \lesssim y \ BoolF \Rightarrow
             \Pi (Functor (y \ BoolF)) \rightarrow
              \mu (\Sigma y) \rightarrow
              \mu (\Sigma (y \ BoolF))
```

We will ignore the already stated complications that arise from subexpressions such as Functor (y \ BoolF) and skip to the step in which we tell desugar what particular row y it operates over. Here we know it must have at least the BoolF and LamF constructors. Let us try something like the following AST, using # as pseudonotation for row concatenation to save space.

```
type AST = BoolF ++ LamF ++
               {'Lit \triangleright const Int , 'Add \triangleright \lambdax. Pair x x }
desugar AST : BoolF \lesssim AST, LamF \lesssim (AST \setminus BoolF) \Rightarrow
                     \Pi (Functor (AST \ BoolF)) \rightarrow
                     \mu (\Sigma y) \rightarrow \mu (\Sigma (AST \ BoolF))
```

When desugar is passed AST for z, the inherent computation in the complement operator is made more obvious. What should AST \ BoolF reduce to? Intuitively, we suspect the following to hold:

```
AST \ BoolF = {'Lit ▶ const Int ,
                      'Add \triangleright \lambda x. Pair x x,
                     'Lam ⊳ Id ,
                      'App \triangleright \lambda x. Pair x x ,
                     'Var ▶ const Nat }
```

But this computation must be realized, just as (analogously) λ -redexes are realized by β -reduction.

Type Equivalence & Reduction

We define reduction on types $\tau \longrightarrow_{\mathcal{T}} \tau'$ by directing the type equivalence judgment $\Delta \vdash \tau = \tau' : \kappa$ from left to right, defined in Figure 2. We omit conversion and closure rules.

3.1 Normal forms

The syntax of normal types is given in Figure 3.

Type variables
$$\alpha \in \mathcal{A}$$
 Labels $\ell \in \mathcal{L}$

Ground Kinds

Kinds

 $\kappa ::= \gamma \mid \kappa \to \kappa \mid R[\kappa]$

Row Literals

Neutral Types

 $\hat{P} \ni \hat{\rho} ::= \{\ell_{i} \triangleright \hat{\tau}_{i}\}_{i \in 0...m}$

Normal Types

 $\hat{T} \ni \hat{\tau}, \hat{\phi} ::= n \mid \hat{\phi} \$ n \mid \hat{\rho} \mid \hat{\pi} \Rightarrow \hat{\tau}$
 $\mid \forall \alpha : \kappa. \hat{\tau} \mid \lambda \alpha : \kappa. \hat{\tau}$
 $\mid n \triangleright \hat{\tau} \mid \ell \mid \# \hat{\tau} \mid \hat{\tau} \setminus \hat{\tau}$
 $\mid \Pi^{(\star)} \hat{\tau} \mid \Sigma^{(\star)} \hat{\tau}$

$$(\kappa_{nf} - \text{NE}) \frac{\Delta \vdash_{ne} n : \gamma}{\Delta \vdash_{nf} n : \gamma} \qquad (\kappa_{nf} - \backslash) \frac{\Delta \vdash_{nf} \hat{\tau}_{i} : R[\kappa]}{\Delta \vdash_{nf} \hat{\tau}_{i} \nearrow \hat{\tau}_{1} : R[\kappa]}$$

$$(\kappa_{nf} - \triangleright) \frac{\Delta \vdash_{ne} n : L}{\Delta \vdash_{nf} \hat{\tau} : \kappa}$$

Labels $\ell \in \mathcal{L}$

Figure 3. Normal type forms

Normalization reduces applications and maps except when a variable blocks computation, which we represent as a neutral type. A neutral type is either a variable or a spine of applications with a variable in head position. We distinguish ground kinds y from functional and row kinds, as neutral types may only be promoted to normal type at ground kind (rule (κ_{nf} -NE)): neutral types n at functional kind must η expand to have an outer-most λ -binding (e.g., to λx . n x), and neutral types at row kind are expanded to an inert map by the identity function (e.g., to $(\lambda x.x)$ \$ n). Likewise, repeated maps are necessarily composed according to rule (E-MAP_o):

$$\begin{array}{c} \Delta \vdash \tau = \tau : \kappa \\ \\ (E \vdash \beta) \frac{\Delta \vdash (\lambda \alpha : \kappa . \tau) \, \upsilon : \kappa'}{\Delta \vdash (\lambda \alpha : \kappa . \tau) \, \upsilon = \tau [\upsilon / \alpha] : \kappa'} \\ \\ (E \vdash \text{LIFT}_\Xi) \frac{\Delta \vdash \rho : R[\kappa_1 \to \kappa_2]}{\Delta \vdash (\Xi^{(\kappa_1 \to \kappa_2)} \rho) \, \tau = \Xi^{(\kappa_2)} (\rho ? ? \tau) : \kappa_2} \\ \text{where } \rho ? ? \tau = (\lambda f. f. \tau) \$ \, \rho \\ \\ (E \vdash \backslash) \frac{\Delta \vdash \{\xi_i \triangleright \tau_i\}_{i \in 0...n} : R[\kappa]}{\Delta \vdash \{\xi_i \triangleright \tau_i\}_{i \in 0...m} : R[\kappa]} \frac{\Delta \vdash \{\xi_i \triangleright \tau_i\}_{j \in 0...m} : R[\kappa]}{\Delta \vdash \{\xi_i \triangleright \tau_i\}} \cdot \{\xi_j \triangleright \tau_j\} : R[\kappa]} \\ \\ (E \vdash \text{MAP}) \frac{\Delta \vdash \phi : \kappa_1 \to \kappa_2}{\Delta \vdash \{\xi_i \triangleright \tau_i\}_{i \in 0...n} : R[\kappa_1]} \frac{\Delta \vdash \rho : R[\kappa]}{\Delta \vdash \phi * \{\xi_i \triangleright \tau_i\}_{i \in 0...n} : R[\kappa_1]} \\ \\ (E \vdash \text{MAP}_i) \frac{\Delta \vdash \rho : \kappa_1 \to \kappa_2}{\Delta \vdash \rho : (\lambda \alpha. \alpha) * \rho : R[\kappa]} \\ \\ (E \vdash \text{MAP}_o) \frac{\Delta \vdash \phi_1 : \kappa_2 \to \kappa_3}{\Delta \vdash \rho : (\lambda \alpha. \alpha) * \rho : R[\kappa]} \frac{\Delta \vdash \rho : R[\kappa_1]}{\Delta \vdash \phi_1 * (\phi_2 \$ \rho) = (\phi_1 \circ \phi_2) \$ \, \rho : \kappa_3} \\ \text{where } \phi_1 \circ \phi_2 = \lambda \alpha. \phi_1 (\phi_2 \alpha) \\ \\ (E \vdash \text{MAP}_{\backslash}) \frac{\Delta \vdash \phi : \kappa_1 \to \kappa_2}{\Delta \vdash \rho : R[\kappa]} \frac{\Delta \vdash \rho : R[\kappa_1]}{\Delta \vdash \phi * (\rho_2 \backslash \rho_1) = \phi * \rho_2 \backslash \phi * \rho_1 : \kappa_2} \\ \\ (E \vdash \Xi) \frac{\Delta \vdash \rho : R[R[\kappa]]}{\Delta \vdash \Xi^{(R[\kappa])} \rho = \Xi^{(\kappa)} * \rho : R[\kappa]} (\Xi \in \{\Pi, \Sigma\}) \\ \\ (E \vdash \pi) \frac{\Delta \vdash \phi : \kappa_1 \to \kappa_2}{\Delta \vdash \phi = \lambda \alpha : \kappa_1.\phi \alpha : \kappa_1 \to \kappa_2} \\ \text{subtract } \rho \rho \\ \text{subtract } \rho \rho \\ \text{subtract } \rho \rho' \qquad \text{if } \ell = \ell' \text{ and } \tau = \tau' \\ \{\ell \vdash \tau, \text{ subtract } \rho \{\ell' \vdash \tau', \rho'\}\} \qquad \text{if } \ell < \ell' \\ \text{subtract } \{\ell \vdash \tau, \rho\} \rho' \qquad \text{if } \ell < \ell' \\ \text{subtract } \{\ell \vdash \tau, \rho\} \rho' \qquad \text{if } \ell < \ell' \\ \text{subtract } \ell \vdash \tau' \text{ of } \ell' \end{cases}$$

Figure 2. Type equivalence

For example, $\phi_1 \$ (\phi_2 \$ n)$ normalizes by letting ϕ_1 and ϕ_2 compose into $((\phi_1 \circ \phi_2) \$ n)$. By consequence of η -expansion, records and variants need only be formed at kind \star . This means a type such as $\Pi(\ell \triangleright \lambda x.x)$ must reduce to $\lambda x.\Pi(\ell \triangleright x)$, η -expanding its binder over the Π . Nested applications of Π and Σ are also "pushed in" by rule (E- Ξ). For example, the type $\Pi \Sigma (\ell_1 \triangleright (\ell_2 \triangleright \tau))$ has Σ mapped over the outer row, reducing to $\Pi(\ell_1 \triangleright \Sigma(\ell_2 \triangleright \tau))$.

The syntax $n \triangleright \hat{\tau}$ separates singleton rows with variable labels from row literals $\hat{\rho}$ with literal labels; rule $(\kappa_{nf} \rightarrow)$ ensures that n is a well-kinded neutral label. A row is otherwise

an inert map $\phi \$ n or the complement of two rows $\hat{\tau_2} \setminus \hat{\tau_1}$. Observe that the complement of two row literals should compute according to rule (e-\); we thus require in the kinding of normal row complements (κ_{nf} -\) that one (or both) rows are not literal so that the computation is indeed inert. The remaining normal type syntax does not differ meaningfully from the type syntax; the remaining kinding rules for the judgments $\Delta \vdash_{nf} \hat{\tau} : \kappa$ and $\Delta \vdash_{ne} n : \kappa$ are as expected.

3.2 Metatheory

3.2.1 Canonicity of normal types. The normal type syntax is pleasantly partitioned by kind. Due to η -expansion of functional variables, arrow kinded types are canonically λ -bound. A normal type at kind R[κ] is either an inert map $\hat{\phi}^*$ n, a variable-labeled row $(n \triangleright \hat{\tau})$, the complement of two rows $\hat{\tau}_2 \setminus \hat{\tau}_1$, or a row literal $\hat{\rho}$. The first three cases necessarily have neutral types (recall that at least one of the two rows in a complement is not a row literal). Hence rows in empty contexts are canonically literal. Likewise, the only types with label kind in empty contexts are label literals; recall that we disallowed the formation of Π and Σ at kind R[L] \to L, thereby disallowing non-literal labels such as $\Delta \not \vdash \Pi \epsilon : L$ or $\Delta \not \vdash \Pi(\ell_1 \triangleright \ell_2) : L$.

Theorem 3.1 (Canonicity). Let $\hat{\tau} \in \hat{\mathcal{T}}$.

- If $\Delta \vdash_{nf} \hat{\tau} : (\kappa_1 \to \kappa_2)$ then $\hat{\tau} = \lambda \alpha : \kappa_1.\hat{v}$;
- $if \in \vdash_{nf} \hat{\tau} : R[\kappa] \ then \ \hat{\tau} = \{\ell_i \triangleright \hat{\tau}_i\}_{i \in 0...m}.$
- If $\epsilon \vdash_{nf} \hat{\tau} : \mathsf{L}$, then $\hat{\tau} = \ell$.

3.2.2 Normalization.

Theorem 3.2 (Normalization). There exists a normalization function $\downarrow : \mathcal{T} \to \hat{\mathcal{T}}$ that maps well-kinded types to well-kinded normal forms.

 \Downarrow is realized in Agda intrinsically as a function from derivations of $\Delta \vdash \tau : \kappa$ to derivations of $\Delta \vdash_{nf} \hat{\tau} : \kappa$. Conversely, we witness the inclusion $\hat{\mathcal{T}} \subseteq \mathcal{T}$ as an embedding $\Uparrow : \hat{\mathcal{T}} \to \mathcal{T}$, which casts derivations of $\Delta \vdash_{nf} \hat{\tau} : \kappa$ back to a derivation of $\Delta \vdash \tau : \kappa$; we omit this function and its use in the following claims, as it is effectively the identity function (modulo tags).

The following properties confirm that \downarrow behaves as a normalization function ought to. The first property, *stability*, asserts that normal forms cannot be further normalized. Stability implies *idempotency* and *surjectivity*.

Theorem 3.3 (Properties of normalization).

- (Stability) for all $\hat{\tau} \in \hat{\mathcal{T}}$, $\downarrow \hat{\tau} = \hat{\tau}$.
- (Idempotency) For all $\tau \in \mathcal{T}$, $\Downarrow (\Downarrow \tau) = \Downarrow \tau$.
- (Surjectivity) For all $\hat{\tau} \in \hat{\mathcal{T}}$, there exists $v \in \mathcal{T}$ such that $\hat{\tau} = \bigcup v$.

We now show that \downarrow indeed reduces faithfully according to the equivalence relation $\Delta \vdash \tau = \tau : \kappa$. Completeness of

normalization states that equivalent types normalize to the same form.

Theorem 3.4 (Completeness). For well-kinded $\tau, v \in \mathcal{T}$ at kind κ , If $\Delta \vdash \tau = v : \kappa$ then $\psi \tau = \psi v$.

Soundness of normalization states that every type is equivalent to its normalization.

Theorem 3.5 (Soundness). For well-kinded $\tau \in \mathcal{T}$ at kind κ , there exists a derivation that $\Delta \vdash \tau = \Downarrow \tau : \kappa$. Equivalently, if $\Downarrow \tau = \Downarrow v$, then $\Delta \vdash \tau = v : \kappa$.

Soundness and completeness together imply, as desired, that $\tau \longrightarrow_{\mathcal{T}} \tau'$ iff $\parallel \tau = \parallel \tau'$.

3.2.3 Decidability of type conversion. Equivalence of normal types is syntactically decidable which, in conjunction with soundness and completeness, is sufficient to show that $R\omega\mu$'s equivalence relation is decidable.

Theorem 3.6 (Decidability). Given well-kinded $\tau, v \in \mathcal{T}$ at kind κ , the judgment $\Delta \vdash \tau = v : \kappa$ either (i) has a derivation or (ii) has no derivation.

4 Normalization by Evaluation (NbE)

This section describes our results' methodology, which is largely inspired by the *normalization by evaluation* algorithm and metatheory of Chapman et al. [2019], although we have made significant extensions to their approach in order to capture the computation of rows. Our work also differs in some design choices (see (§6)). Our full development is available as part of the anonymous supplementary materials. The code we present here is summarized and tidied for display in print and easier digestion, but otherwise remains faithful to the development in behavior and intent. The claims of this section are annotated with the corresponding points in our full artifact.

Normalization by evaluation comes in a handful of different flavors. In our case, we seek to build a normalization function $\Downarrow: \mathcal{T} \to \hat{\mathcal{T}}$ by interpreting derivations in $\mathcal{T}^{\kappa}_{\Lambda}$ (the set of derivations of the judgment $\Delta \vdash \tau : \kappa$) into a semantic domain capable of performing reductions semantically. We then reify objects in the semantic domain back to judgments in $\hat{\mathcal{T}}^{\kappa}_{\Lambda}$ (the set of derivations of the judgment $\Delta \vdash_{nf} \tau : \kappa$). The mapping of syntax to a semantic domain is typically written as $[\cdot]$ and called the *residualizing semantics*. For example, a judgment of the form $\Delta \vdash \phi : \star \rightarrow \star$ could be interpreted into a set-theoretic function, allowing applications to be interpreted into set-theoretic applications by that function. In our case, the syntax of the judgments $\Delta \vdash \tau : \kappa$, $\Delta \vdash_{nf} \tau : \kappa$, and $\Delta \vdash_{ne} \tau : \kappa$ are represented as Agda data types (where Env is a list of De Bruijn indexed type variables and Kind is the type of kinds):

```
SemType : Env \rightarrow Kind \rightarrow Set

SemType \Delta \star = NormalType \Delta \star

SemType \Delta L = NormalType \Delta L

SemType \Delta_1 (\kappa_1 '\rightarrow \kappa_2) = KripkeFunction \Delta_1 \kappa_1 \kappa_2

SemType \Delta R[ \kappa ] =

RowType \Delta (\lambda \Delta' \rightarrow SemType \Delta' \kappa) R[ \kappa ]
```

Figure 4. Semantic types

```
data Type : Env \to Kind \to Set data NormalType : Env \to Kind \to Set data NeutralType : Env \to Kind \to Set
```

4.1 Residualizing semantics

We define our semantic domain in Agda recursively over the syntax of Kinds in Figure 4.

Types at ground kind \star and L are simply interpreted as NormalTypes. We interpret arrow-kinded types as *Kripke function spaces*, which permit the application of interpreted function ϕ at any environment Δ_2 provided a renaming from Δ_1 into Δ_2 .

```
\begin{array}{lll} \operatorname{Renaming} \Delta_1 & \Delta_2 = \operatorname{TVar} \Delta_1 \; \kappa \; \to \; \operatorname{TVar} \Delta_2 \; \kappa \\ \operatorname{KripkeFunction} \; : \; \operatorname{Env} \; \to \; \operatorname{Kind} \; \to \; \operatorname{Kind} \; \to \; \operatorname{Set} \\ \operatorname{KripkeFunction} \Delta_1 \; \; \kappa_1 \; \; \kappa_2 = \; \forall \; \{\!\Delta_2\!\} \; \to \\ \operatorname{Renaming} \Delta_1 \; \Delta_2 \to \; \operatorname{SemType} \Delta_2 \; \; \kappa_1 \; \to \; \operatorname{SemType} \Delta_2 \; \kappa_2 \end{array}
```

The first three equations thus far are standard for this style of Agda mechanization, borrowing from Chapman et al. [2019]. Novel to our development is the interpretation of row-kinded types. First, we define the interpretation of row literals as finitely indexed maps to label-type pairs. (Here the type Label is a synonym for String, but could be any type with decidable equality and a strict total-order.)

```
Row : Set \rightarrow Set
Row A = \exists[ n ](Fin n \rightarrow Label \times A)
```

Next, we define a RowType inductively as one of four cases: either a row literal constructed by row, a neutral-labeled row singleton constructed by _>_, an inert map constructed by _\$_, or an inert row complement constructed by __ (Figure 5).

Care must be taken to explain some nuances of each constructor. First, the row and __ constructors are each constrained by predicates. The OrderedRow ρ predicate asserts that ρ has its string labels totally and ascendingly ordered—guaranteeing that labels in the row are unique and that rows are definitionally equal modulo ordering. The NotRow ρ predicate asserts simply that ρ was not constructed by row. In other words, it is not a row literal. This is important, as the complement of two row literals should reduce to a Row, so we must disallow the formation of complements in which at least one of the operands is a literal.

```
data RowType (\Delta : Env)
                       (T : Env \rightarrow Set) : Kind \rightarrow Set where
                    : (\rho : Row (T \Delta)) \rightarrow
   row
                         OrderedRow \rho \rightarrow
                         RowType \Delta T R[ \kappa ]
                  : NeutralType \Delta L \rightarrow
                       T \Delta \rightarrow
                       RowType \Delta T R[ \kappa ]
    _{\$}: (\forall \{\Delta'\} \rightarrow
                            Renaming \Delta \Delta' \rightarrow
                            NeutralType \Delta' \kappa_1 \rightarrow
                            T \Delta') \rightarrow
                       NeutralType \Delta R[ \kappa_1 ] \rightarrow
                       RowType \Delta T R[\kappa_2]
   \_\setminus\_ : (\rho_2 \ \rho_1 : RowType \Delta T R[ \kappa ]) <math>\rightarrow
                       {nor : NotRow \rho_2 or notRow \rho_1} \rightarrow
                       RowType \Delta T R[ \kappa ]
```

Figure 5. Semantic row type

The next set of nuances come from dancing around Agda's positivity and termination checking. It would have been preferable for us to have written the row and _\$_ constructors as follows:

Such a definition would have necessarily made the types RowType and SemType mutually inductive-recursive. But this would run afoul of Agda's termination and positivity checkers for the following reasons:

- 1. in the constructor row, the input Row (SemType $\Delta \kappa$) makes a recursive call to SemType $\Delta \kappa$, where it's not clear (to Agda) that this is a strictly smaller recursive call. To get around this, we parameterize the RowType type by T: Env \rightarrow Set so that we may enforce this recursive call to be structurally smaller—hence the definition of SemType at kind R[κ] passes the argument (λ Δ ' \rightarrow SemType Δ ' κ), which varies in environment but is at a strictly smaller kind.
- 2. The _\$_ constructor takes a KripkeFunction as input, in which SemType Δ' κ₁ occurs negatively, which Agda must outright reject. Here we borrow some clever machinery from Allais et al. [2013] and instead make the KripkeFunction accept the input NeutralType Δ' κ₁, which is already defined. The trick is that, as we will

```
reflect : NeutralType \Delta \ \kappa \to \mathrm{SemType} \ \Delta \ \kappa reify : \mathrm{SemType} \ \Delta \ \kappa \to \mathrm{NormalType} \ \Delta \ \kappa reflect \{\kappa = \star\} \ \tau = \mathrm{ne} \ \tau reflect \{\kappa = \mathsf{L}\} \ \tau = \mathrm{ne} \ \tau reflect \{\kappa = \mathsf{K}_1 \ ' \to \kappa_2\} = \lambda \ r \ v \to \mathrm{reflect} \ ((\mathrm{rename} \ r \ \tau) \cdot \mathrm{reify} \ v) reflect \{\kappa = \mathsf{R}[\ \kappa \ ]\} \ \rho = (\lambda \ r \ n \to \mathrm{reflect} \ n) \ \$ \ \rho
```

Figure 6. Reflection

show in the next section, every NeutralType may be promoted to a SemType. In practice this is sufficient for our needs.

4.2 Reflection & reification

We have now declared three domains: the syntax of types, the syntax of normal and neutral types, and the embedded domain of semantic types. Normalization by evaluation involves producing a *reflection* from neutral types to semantic types, a *reification* from semantic types to normal types, and an *evaluation* from types to semantic types. It follows thereafter that normalization is the reification of evaluation. Because we reason about types modulo η -expansion, reflection and reification are necessarily mutually recursive. (This is not the case however with e.g. Chapman et al. [2019].)

Reflection is defined in Figure 6. Types at kind \star and L can be promoted straightforwardly with the ne constructor. Neutral types at arrow kind must be expanded into Kripke functions. Note that the input v has type SemType Δ κ_1 and must be reified; additionally, τ is kinded in environment Δ_1 and so must be renamed to Δ_2 , the environment of v. The syntax · is used to construct an application of a neutralType to a normalType. Finally, a neutral row (e.g., a row variable) must be expanded into an inert mapping by (λ r n \rightarrow reflect n), which is effectively the identity function.

The definition of reification is a little more involved (Figure 7). The first two equations are expected (τ is already in normal form). Functions are reified effectively by η -expansion; note that we are using intrinsically-scoped De Bruijn variables, so Z constructs the zero'th variable and S induces a renaming in which each variable is incremented by one. (Recall that ϕ is a Kripke function space and so expects a renaming as argument.) The constructor `promotes a type variable to a neutralType, which is reflected so that it may be passed to ϕ S. The remaining equations describe the reification of the four row cases. When the input is a neutral-labeled row singleton, we need only create a NeutralType-labeled singleton with the body τ reified. The case of an inert complement $\rho_2 \setminus \rho_1$ remains an inert complement at type NormalType. Finally, we reify the inert map ϕ \$\tau\$ rby reifying ϕ analogously

```
reify \{\kappa = \star\} \tau = \tau
661
        reify \{\kappa = L\} \tau = \tau
662
        reify \{\kappa = \kappa_1 ' \rightarrow \kappa_2\} \phi =
663
           \lambda (reify (\phi S (reflect (\lambda Z)))
664
        reify \{\kappa = R[\kappa]\}\ (l > \tau) = l > (reify \tau)
        reify \{\kappa = R[\kappa]\} (\rho_2 \setminus \rho_1) = reify \rho_2 \setminus reify \rho_1
666
        reify \{\kappa = R[\kappa]\} (\phi \ \tau) =
667
           \lambda (reify (\phi S (\lambda Z))) $ (reify \tau)
668
        reify \{\kappa = R[\kappa]\} (row \rho q) =
669
           row (reifyRow \rho) (reifyPreservesOrdering q)
670
           where
671
              reifyRow : Row (SemType \Delta \kappa) \rightarrow
672
                              List (Label \times NormalType \Delta \kappa)
673
              reifyRow (0, P) = []
674
              reifyRow (suc n , P) with P fzero
675
              ... | (1, \tau) =
                 (1 , reify \tau) :: reifyRow (n , P \circ fsuc)
677
```

Figure 7. Reification

to the $\kappa_1 \to \kappa_2$ case and mapping it over the reification of τ .

The equation of interest is in reifying row literals. We pun the row constructor to construct row literals at type NormalType, which likewise expects a proof that the row is well-ordered. Such a proof is given by the auxiliary lemma reifyPreservesOrdering. We use a helper function reifyRow to recursively build a list of Label-NormalType pairs (that is, the form of NormalType row literals) from a semantic row. The empty case is trivial; the successor case must inspect the head of the list by destructing P fzero, i.e., the label-type association of the zero'th finite index. From there we yield a semantic type τ which we reify and append to the result of recursing.

Finally, we have asserted that types are reduced modulo β -reduction and η -expansion. It follows that a given NeutralType should, after reflection and reification, end up in an expanded form. This is precisely how we define the promotion of NeutralTypes to NormalTypes:

```
\eta\text{-norm} : NeutralType \Delta \kappa \rightarrow NormalType \Delta \kappa \eta\text{-norm} = reify \circ reflect
```

This function is necessary: the NormalType constructor ne stipulates that we may only promote neutral derivations to normal derivations at *ground kind* (rule (κ_{nf} -NE)). Hence η -norm is the only means by which we may promote neutral types at row or arrow kind.

4.3 Helping evaluation

We will build our evaluation function incrementally; we find it clearer to incrementally build helpers for sub-computation (e.g., mapping or the complement) on our way up to full evaluation. We describe these helpers next.

```
_$'_ : SemType \Delta (\kappa_1 '\rightarrow \kappa_2) \rightarrow SemType \Delta R[ \kappa_1 ] \rightarrow SemType \Delta R[ \kappa_2 ] \phi $' (1 \triangleright \tau) = 1 \triangleright (\phi ·' \tau) \phi $' (row (n , P) q) = row (n , fmap (\phi id) \circ P) \phi $' (\rho_2 \ \rho_1) = (\phi $ \rho_2 \ (\phi $ \rho_1) \phi_1 $' (\phi_2 $ n) = (\phi $ \phi_2 \ (\phi $ \phi_3 ) $ n
```

Figure 8. Semantic mapping

4.3.1 Semantic application. We define semantic application straightforwardly as Agda application under the identity renaming.

```
_.'_ : SemType \Delta (\kappa_1 '\to \kappa_2) \to SemType \Delta \kappa_1 \to SemType \Delta \kappa_2 \phi .' v = \phi id v
```

- **4.3.2 Semantic mapping.** Mapping over rows is a form of computation novel to $R\omega\mu$'s equivalence relation. We define the mapping ϕ \$ ρ over the four cases a semantic row may take (Figure 8). When ρ is neutral-labeled, we simply apply ϕ to its contents. The case where ρ is a row literal is interesting in that our choice of representation for row literals as Agda functions comes to pay off: we may express the mapping of ϕ across the row (n , P) by pre-composing P with ϕ (note that we must appropriately fmap ϕ over the pair's second component). The mapping of ϕ over a complement is distributive, following rule (E-MAP()). Likewise, we follow rule (E-MAP()) in grouping the nested map ϕ \$ (ϕ_2 \$ n) into a composed map.
- **4.3.3 Semantic complement.** The complement of two row-kinded semantic types is always inert when one (or both) are not row literals, and thus constructed simply by the __ constructor. The interesting case is when we must reduce two row literals to another row literal (Figure 9). Here our implementation differs slightly to the syntactic presentation in Figure 2. We proceed by induction on the length of the left-hand row: The resulting row is the empty row 0 , λ () when the left-hand row is empty. (That is to say, an empty row minus any other row is empty.) Otherwise, we check if the label of the head entry in P, P fzero .fst, is in the right-hand row. If so, we omit it and proceed with recursion. If not, we retain it.
- **4.3.4 Semantic flap.** The rule (E-LIFT Ξ) describes how Π and Σ reassociate from e.g. (Π ρ) a to Π (ρ ?? a). We define a semantic version of the flap (flipped map) operator as follows:

```
_??'_ : SemType \Delta R[ \kappa_1 '\rightarrow \kappa_2 ] \rightarrow SemType \Delta \kappa_1 \rightarrow SemType \Delta R[ \kappa_2 ] \phi ??' a = (\lambda r f \rightarrow f \cdot' (rename r a)) $' \phi
```

4.3.5 Semantic Π **and** Σ **.** The defining equations for the reduction of Π is given in Figure 10. (The logic for Σ is identical and omitted.)

```

Figure 10. Semantic Π

The input row to Π' has kind $R[\kappa]$; we proceed by destructing κ . Recall that we may only construct record types in normal form at kind \star , and so for the case that $\kappa = \star$ we simply reify the input and construct the record via the NormalType constructor Π . We exclude the case that $\kappa = L$ because it is impossible: in the Type syntax, we restrict the formation of the Π constructor by the following predicate:

```
NotLabel : Kind \rightarrow Set

NotLabel \star = T

NotLabel L = \bot

NotLabel (\kappa_1 \ ' \rightarrow \kappa_2) = NotLabel \kappa_2

NotLabel R[ \kappa ] = NotLabel \kappa
```

This is to say, one may not apply Π to an input that is a row of labels, a label-valued function, or a nested row of labels. Next, when applying Π' to a function, we must expand the semantic λ -binding outwards. Thereafter, we apply rule (e-lift) to explain how Π' operates on a single operand. Finally, we implement rule (e- Ξ) directly in the last equation: the application of Π' to a row-kinded input x is simply the mapping of Π' over x.

4.4 Evaluation

Evaluation warrants an environment that maps type variables to semantic types. The identity environment, which fixes the meaning of variables, is given as the composition of reflection and `, the constructor of NeutralTypes from TVars.

```
\begin{array}{lll} \operatorname{SemEnv} : & \operatorname{Env} \to \operatorname{Env} \to \operatorname{Set} \\ \operatorname{SemEnv} \Delta_1 & \Delta_2 = \operatorname{TVar} \Delta_1 \, \kappa \, \to \, \operatorname{SemType} \Delta_2 \, \kappa \\ \operatorname{idEnv} : & \operatorname{SemEnv} \, \Delta \, \Delta \\ \operatorname{idEnv} = & \operatorname{reflect} \, \circ \, \, \\ \end{array}
```

We describe only the interesting cases of evaluation (Figure 11); the rest are purely compositional.

```
eval : Type \Delta_1 \to \operatorname{SemEnv} \Delta_1 \ \Delta_2 \to \operatorname{SemType} \Delta_2 \ \kappa
eval (`x) \eta = \eta x
eval (\tau_1 \cdot \tau_2) \eta = (\text{eval } \tau_1 \ \eta) \cdot ' (\text{eval } \tau_2 \ \eta)
eval (\rho_2 \setminus \rho_1) \eta = eval \rho_2 \eta \setminus eval \rho_1 \eta
eval (\lambda \tau) \eta = \lambda r v \rightarrow
   eval \tau (extend (rename r \circ \eta) v)
eval \Pi \eta = \lambda r v \rightarrow \Pi' v
eval \Sigma \eta = \lambda r v \rightarrow \Sigma' v
eval (\phi \ \$ \ \tau) \eta = eval \phi \ \eta \ \$' eval n \tau
eval (1 > \tau) \eta with eval 1 \eta
... | ne n = (n \triangleright eval \tau \eta)
... | lab \ell = row (1 , \lambda { fzero \rightarrow
                                                 (\ell , eval \tau \eta )}) tt
eval (row \rho q) \eta = row
   (evalRow \rho \eta)
   (evalPreservesOrdering q)
   evalRow : List (Label \times (Type \Delta_1 \kappa)) \rightarrow
                     SemEnv \Delta_1 \Delta_2 \rightarrow
                     Row (SemType \Delta_2 \kappa)
   evalRow [] \eta = 0 , \lambda ()
   evalRow ((1 , \tau) :: \rho) \eta = \lambda { fzero \rightarrow eval \tau \eta ,
                                              fsuc \_ \rightarrow \text{evalRow } \rho \eta }
```

Figure 11. Evaluation

The first equation states that variables evaluate to their meaning in environment η . The equations for application \cdot , row complement \setminus , record and variant operators Π and Σ , and mapping $_{\pm}$ defer to the semantic helpers defined in (§4.3). The evaluation of a function $\lambda \tau$ is simply the evaluation of the body in the environment η expanded with semantic object v, being careful to rename appropriately as this is a Kripke function. Evaluation of labeled singletons must check if the label is a neutral variable n or label literal ℓ ; in the former case, we evaluate to an inert singleton using the RowType constructor _>_; in the latter, we evaluate to a row literal in which fzero points to (ℓ , eval τ η). The term tt : Unit is the evidence that this row literal is trivially ordered. Finally, we evaluate row literals by recursion: the empty case evaluates to the empty Row, 0, λ (); the cons case evaluates to a row in which fzero maps to the evaluation of τ , while fsuc otherwise proceeds recursively. Again, we have an obligation to prove that evaluation preserves the ordering evidence q, which is performed by the auxiliary lemma evalPreservesOrdering.

4.5 Normalization

Normalization in the NbE approach is simply the composition of reification after evaluation.

```
\label{eq:continuity} \begin{array}{l} \downarrow : \ \mathsf{Type} \ \Delta \ \kappa \ \longrightarrow \ \mathsf{NormalType} \ \Delta \ \kappa \\ \downarrow \ \tau \ = \ \mathsf{reify} \ (\mathsf{eval} \ \tau \ \mathsf{idEnv}) \end{array}
```

It will be helpful in the coming metatheory to define an inverse embedding by induction over the NormalType structure. The definition is entirely expected and omitted.

```
\label{eq:constraints} \begin{array}{l} \Uparrow: \mbox{ NormalType } \Delta \ \kappa \ \to \mbox{ Type } \Delta \ \kappa \\ \mbox{$\Uparrow$NE : NeutralType } \Delta \ \kappa \ \to \mbox{ Type } \Delta \ \kappa \end{array}
```

5 Mechanized metatheory

This section describes the Agda formalization of the metatheory summarized in (§3.2), including proofs and proof outlines where space permits.

5.1 Canonicity of normal types

Normal forms are partitioned by kind, which can easily be shown by case splitting on NormalType inputs. We first demonstrate that neutrals cannot exist in an empty environment:

```
noNeutrals : NeutralType [] \kappa \to \bot noNeutrals (n \cdot \tau) = noNeutrals n
```

Now, in any context an arrow-kinded type is canonically λ -bound:

```
arrow-canonicity : (\phi: \text{NormalType } \Delta \ (\kappa_1 \ ' \to \kappa_2)) \to \exists [ \ \tau \ ] (\phi \equiv \ `\lambda \ \tau) arrow-canonicity (\ `\lambda \ \tau) = \tau \ , \ \text{refl}
```

A row in an empty context is necessarily a row literal (all omitted cases are eliminated by \bot -elim):

```
row-canonicity : (\rho: \text{NormalType } [] R[\kappa]) \rightarrow \exists [ (xs, oxs) ]

(\rho \equiv \text{row xs oxs})

row-canonicity (\text{row } \rho \text{ q}) = \rho, q, refl
```

And a label-kinded type is necessarily a label literal (where lab constructs a label literal):

```
label-canonicity : (l : NormalType [] L) \rightarrow \exists[ \ell ] (l \equiv lab \ell) label-canonicity (ne x) = \bot-elim (noNeutrals x) label-canonicity (lab s) = s , refl
```

5.2 Stability

Stability follows by simple induction on the input derivation $\Delta \vdash_{nf} \tau : \kappa$. Here it is clearer that we are stating \Downarrow is left-inverse to \Uparrow .

```
Stability : \forall (\tau : NormalType \Delta \kappa) \rightarrow \downarrow (\uparrow \tau) \equiv \tau Stability implies idempotency: idempotency : \forall (\tau : Type \Delta \kappa) \rightarrow (\uparrow \circ \downarrow \circ \uparrow \circ \downarrow) \tau \equiv (\uparrow \circ \downarrow) \tau
```

idempotency τ rewrite (stability ($\parallel \tau$)) = refl

```
and surjectivity:
```

```
surjectivity : \forall (\tau : NormalType \Delta \kappa) \rightarrow \exists[ v] (\Downarrow v \equiv \tau) surjectivity \tau = (\uparrow \tau, stability \tau)
```

Dual to surjectivity, stability also implies that embedding is injective.

```
_{\sim} _{\kappa} = \star _{\tau_1} \tau_2 = \tau_1 \equiv \tau_2
_{\sim} {\kappa = L} \tau_1 \tau_2 = \tau_1 \equiv \tau_2
= \approx \{ \kappa = \kappa_1 \rightarrow \kappa_2 \} \phi_1 \phi_2 = 
          Uniform \phi_1 \times Uniform \phi_2 \times PointEqual \phi_1 \phi_2
_{\sim} {\kappa = R[ \kappa ]} (\ell_1 \triangleright \tau_1) (\ell_2 \triangleright \tau_2) = \ell_1 \equiv \ell_2 \times \tau_1 \approx \tau_2
_{\sim} {\kappa = R[ \kappa_2 ]} (_$_ {\kappa_1} \phi_1 n_1) (_$_ {\kappa_1'} \phi_2 n_2) =
           \exists [ pf : \kappa_1 \equiv \kappa_1' ]
                       UniformNE \phi_1 \times
                       UniformNE \phi_2 \times
                       PointEqualNE (convKripkeNE pf \phi_1) \phi_2 \times
                        convNE pf n_1 \equiv n_2
_{\sim} {\kappa = R[ \kappa ]} (\rho_2 \setminus \rho_1) (\rho_4 \setminus \rho_3) = \rho_2 \approx \rho_4 \times \rho_1 \approx \rho_3
_{\sim} _{\sim}
            where
                         (\ell_1, \tau_1) \approx 2 (\ell_2, \tau_2) = \ell_1 \equiv \ell_2 \times \tau_1 \approx \tau_2
                         (n, P) \approx R (m, Q) = \exists [pf : n \equiv m]
                                                                                                                                                            (\forall (i : fin m) \rightarrow
                                                                                                                                                            (subst-Row pf P) i \approx 2 \ Q \ i)
```

Figure 12. Completeness relation

5.3 A logical relation for completeness

Completeness states that equivalent types reduce to the same normal forms. We define the equivalence relation of Figure 2 as an inductive, intrinsically typed relation in Agda.

We prove completeness via a logical relation $_{\sim}$ on semantic types that specifies when two semantic objects are equivalent modulo uniformity ([Allais et al. 2013; Chapman et al. 2019]) and pointwise functional extensionality. We define $_{\sim}$ recursively over the kinds of the inputs τ_1 and τ_2 (Figure 12).

The completeness logical relation is defined compositionally in the cases where $\kappa = \star$, $\kappa = \bot$, or $\kappa = \mathbb{R}[\ \kappa\]$ and the equated rows are neutral-labeled or inert complements. In the case that $\kappa = \kappa_1 \rightarrow \kappa_2$, we assert that the Kripke functions ϕ_1 and ϕ_2 are *uniform* and *extensionally equivalent* to one another (Figure 13). Uniformity and states effectively that passing a renaming r_2 to a Kripke function applied to its argument is equivalent to renaming it algorithmically. The uniformity property is attributable to Allais et al.

```
Uniform : KripkeFunction \Delta \kappa_1 \ \kappa_2 \to \mathrm{Set}  
Uniform \phi = \forall \ (r_1 : \mathrm{Renaming} \ \Delta_1 \ \Delta_2)  
 (r_2 : \mathrm{Renaming} \ \Delta_2 \ \Delta_3)   
 (v_1 \ v_2 : \mathrm{SemType} \ \Delta_2 \ \kappa_1) \to   
 v_1 \approx v_2 \to   
 \mathrm{rename} \ r_2 \ (\phi \ r_1 \ v_1) \approx   
 \phi \ (r_2 \circ r_1) \ (\mathrm{rename} \ r_2 \ v_2)   
PointEqual : (\phi_1 \ \phi_2 : \mathrm{KripkeFunction} \ \Delta \kappa_1 \ \kappa_2) \to \mathrm{Set}  
PointEqual \phi_1 \ \phi_2 = \forall \ (\mathrm{r} : \mathrm{Renaming} \ \Delta_1 \ \Delta_2)   
 \{v_1 \ v_2 : \mathrm{SemType} \ \Delta_2 \kappa_1\} \to   
 v_1 \approx v_2 \to   
 \phi_1 \ \mathrm{r} \ v_1 \approx \phi_2 \ \mathrm{r} \ v_2
```

Figure 13. Uniformity and point equality

[2013] but simplified drastically by Chapman et al. [2019]. The PointEqual predicate circumvents any need to postulate functional extensionality; rather, we assert that ϕ_1 and ϕ_2 map equivalent inputs to equivalent outputs (a property to be expected of a logical relation).

The predicates UniformNE and PointEqualNE are entirely analogous to Uniform and PointEqual except that they describe Kripke functions in which the domain is a NeutralType rather than SemType. In the case that we are equating two inert maps, we must additionally assert that the domains of ϕ_1 and ϕ_2 (that is, κ_1 and κ_1 ', resp.) are equivalent. The helpers convKripkeNE and convNE convert ϕ_1 and n_1 appropriately so to be indexed by kind κ_1 '.

Finally, we equate row literals under the \approx R relation, which states that (i) the two rows' lengths are equal, and (ii) the two rows have pointwise related contents. Note that we must use an auxiliary helper subst-Row to convert the length n indexing P to be m.

5.3.1 Properties. Propositionally equal neutral types reflect to equivalent semantic objects:

```
reflect-\approx : \forall {\tau_1 \tau_2 : NeutralType \Delta \kappa} \rightarrow \tau_1 \equiv \tau_2 \rightarrow \text{reflect } \tau_1 \approx \text{reflect } \tau_2
```

Dually, equivalent semantic objects reify to propositionally equal types.

5.3.2 Logical environments. We lift the relation $_{\sim}$ to a relation on semantic environments η_1 and η_2 by asserting that the two are pointwise related.

```
_{\sim}e__ : (\eta_1 \ \eta_2 : SemEnv \Delta_1 \ \Delta_2) \rightarrow Set
\eta_1 \approx \theta \ \eta_2 = \forall \ (\alpha : TVar \Delta_1 \kappa) \rightarrow (\eta_1 \alpha) \approx (\eta_2 \alpha)
```

The identity semantic environment relates to itself under the reflection of propositional equality, as witnessed by $idEnv-\approx$.

```
\label{eq:denv-alpha} \begin{split} \mathrm{idEnv} &\approx \mathrm{idEnv} \approx \mathrm{idEnv} \\ \mathrm{idEnv} &\approx \alpha = \mathrm{reflect} {\approx} \ \mathrm{refl} \end{split}
```

5.3.3 The fundamental theorem and completeness.

The fundamental theorem for the completeness relation states that equivalent types evaluate to related semantic objects. The proof of the fundamental theorem is by induction over the type equivalence witness $\tau_1 \equiv t \tau_2$.

```
fundC : \eta_1 \approx \eta_2 \rightarrow \tau_1 \equiv t \ \tau_2 \rightarrow eval \tau_1 \ \eta_1 \approx \text{eval } \tau_2 \ \eta_2
```

Completeness follows from the fundamental theorem in the identity semantic environment.

```
completeness : \forall \tau_1 \tau_2. \tau_1 \equiv t \tau_2 \rightarrow \psi \tau_1 \equiv \psi \tau_2
completeness \tau_1 \tau_2 eq = reify-\approx (fundC idEnv-\approx eq)
```

5.4 A logical relation for soundness

Soundness states the converse of completeness: if two types normalize to the same form, then they are equivalent.

In practice, it is easier to instead prove that each type is equivalent to its embedded normalization:

```
soundness : \forall (\tau : Type \Delta \kappa) \rightarrow \tau \equiv t \uparrow (\downarrow \tau)
```

trans (soundness τ_1) (embed- \equiv t eq)

And it is straightforward to show that the latter implies the former:

```
embed-\equivt : \forall (\tau_1 : NormalType \Delta \kappa) (\tau_2 : Type \Delta \kappa) \rightarrow \tau_1 \equiv (\downarrow \downarrow \tau_2) \rightarrow \uparrow \tau_1 \equivt \tau_2 embed-\equivt refl = sym (soundness \tau_2) conv-completeness \tau_1 \tau_2 eq =
```

We define a logical relation for soundness by relating un-normalized types to semantic objects in Figure 14. The first two cases state that τ relates to v at ground kind when τ is equivalent to the embedding of v. Figure 16 describes when syntactic type operators relate to Kripke functions; the definitions are largely the same for semantic and neutral Kripke functions except that, in the neutral case, we require instead that τ is equivalent to the η -expansion of n. The definitions otherwise assert that related inputs map to related outputs.

- 5.4.3 The fundamental theorem and Soundness.

5.5 Decidability of type conversion

6 Most closely related work

Our technical development owes a huge debt to two papers in particular. We closely follow the formalization patterns and proof techniques of Chapman et al. [2019]; indeed, this paper is in some sense an extension of their work from System F $\omega\mu$ to system R $\omega\mu$. In turn, Chapman et al. [2019] themselves follow closely Allais et al. [2013], from whom we looked to

in finding the correct semantic image of rows (borrowing from their semantic image of lists). Our paper differs in a few key ways. Firstly, we introduce label and row kinds to the syntax, incurring an additional burden to reduce row maps, the row operators Π and Σ , and row complements. We also reason about types modulo η -equivalence of functions and also expansion of rows to inert maps, which made many proof definitions harder to define. (For example, Chapman et al. [2019] do not need a mutually recursive reify and reflect, which in turn made many auxiliary lemmas harder to define.)
